SIMULATING SIZE-CONSTRAINED GALTON-WATSON TREES

Luc Devroye

September 5, 2011

ABSTRACT. We discuss various methods for generating random Galton-Watson trees conditional on their sizes being equal to $n$. A linear expected time algorithm is proposed.

Author’s address: Luc Devroye, School of Computer Science, McGill University, 3480 University Street, Montreal, Canada H3A 2K6. Research was supported by NSERC Grant A3456 and FQRNT Grant 90-ER-0291.
Introduction

A Galton-Watson tree (Athreya and Ney, 1972) is an ordered tree in which all nodes independently produce offspring distributed as $\xi$. They are called subcritical, critical, and supercritical, according to whether $E(\xi)$ is $< 1$ (subcritical), $= 1$ (critical), or $> 1$ (supercritical). We exclude the trivial cases $\xi < 1$ and $\xi > 1$. The size of a Galton-Watson tree $T$ is denoted by $|T|$. The purpose of this note is to discuss methods for the generation of $T$, conditional on $|T| = n$.

The size-conditioned Galton-Watson trees are important in combinatorial analysis, as they correspond (Kennedy, 1975) to the so-called “simply generated trees” of Moon and Meir (1970, 1978) (see also Moon, 1970). A random conditional Galton-Watson tree has the same distribution as a random simply generated tree picked uniformly from a set of such trees. That particular set depends, of course, on the distribution of $\xi$. For example, the distribution $(1/4, 1/2, 1/4)$ on $\{0, 1, 2\}$ yields a uniform random binary tree, or Catalan tree. The distribution $(1/3, 1/3, 1/3)$ on $\{0, 1, 2\}$ yields a uniform unary-binary tree, or Motzkin tree. The geometric distribution $1/2^{i+1}$, $i \geq 0$, yields the uniform random planted plane tree studied by DeBruijn and Knuth (1972). And the Poisson distribution yields a random rooted labeled tree, or rooted Cayley tree.

For simply generated trees, no generally applicable efficient method has been published to our knowledge. The Boltzmann sampler of Duchon, Flajolet, Louchard and Schaeffer (2001, 2002, 2004) is a general linear time procedure that is easy to implement, but it yields random Galton-Watson trees of random size near $n$. Using rejection, one can generate random trees with their method until the size is right, but then the complexity is superlinear.

For random Catalan trees, several linear-time methods exist. They are often based on equivalences between these trees and other structures such as strings of $n$ balanced parentheses, or simple walks of length $2n$ that remain positive, and start and end at the origin, or Dyck paths. Arnold and Sleep (1980) propose an elegant $O(n)$ algorithm for Catalan trees, which uses an incremental tree construction based on preserving uniformity every step of the way. Their algorithm is genetically linked to the general recursive method of Nijenhuis and Wilf (1978) (see also Flajolet, Zimmerman and van Cutsem, 1994). Another linear time algorithm is described in Alonso, Rémy and Schott (1997a, 1997b), who provide a slightly more general “codeword” method that also covers other trees. Related work can be found in Rémy (1985), Alonso (1992), Alnos and Schott (1995), Mäkinen and Siltanen (1999), Siltanen (2000), Gouyou-Beauchamps (1993, 2003), Hickey and Cohen (1983), Banderier, Bousquet-Mélou, Denise, Flajolet, Gardy and Gouyou-Beauchamps (2002) and Barucci, Del Lungo and Pergola (1992, 1999). Devroye (1986) provides an early survey of various methods for Catalan trees. See Mäkinen (1999) for another survey. Finally, Luczak and Winkler (2004) give an incremental algorithm for growing random Catalan trees one node at a time such that for each $n$, the partial trees are uniformly random.

Via the well-known equivalence between an ordered tree on $n$ nodes and a binary tree on $n-1$ nodes, we can thus also generate a random rooted ordered tree in linear time. Such trees correspond to conditional Galton-Watson processes with $\xi$ geometrically distributed with parameter $1/2$.

The Cayley trees have an equally extensive history. Various representations exist that explicitly explain the number $n^{n-2}$ of labeled free trees of size $n$, typically based on a one-to-one mapping between an $n-2$-vector drawn from $\{1, \ldots, n\}^{n-2}$ and such labeled (unrooted) trees. One of these is Prüfer’s code (1918). Linear time algorithms can convert representations to trees and vice versa. For the Pruefer code, this was in the thesis of Klingsberg (1977) at the University of Washington (see also Devroye (1986)).
Random rooted labeled free trees, of which there are $n^{n-1}$, are in fact nothing but Galton-Watson trees conditioned on size $n$ when the number of children has the Poisson distribution.

The purpose of the present note is to provide a universal linear expected time algorithm for all conditional Galton-Watson trees for which $E\{\xi^2\} < \infty$.

Preliminaries

The distribution of $\xi$ is determined by the probabilities $p_i = P\{\xi = i\}$. Consider the family of distributions parametrized by $\theta > 0$, having $q_i = cp_i\theta^i$, $i \geq 0$, where $c = 1/\sum_i p_i\theta^i$ is a normalization constant. The range for $\theta$ is $(0, \rho)$, where $\rho$, possibly infinite, is the radius of convergence. It is well-known (Kennedy, 1975) that conditioning on $|T| = n$ makes all the trees in this parametrized family identically distributed—the value of $\theta$ does not matter! For this reason, but also for other reasons, it helps to pick a canonical member with mean one, the critical distribution. Thus, we assume throughout that $E\{\xi\} = 1$, and that $p_1 \neq 1$.

There is also the thorny issue of the span $d$ of $\xi$, the greatest common divisor of all $i \geq 1$ for which $p_i > 0$. If $d = 1$, then there exists $n_0$ such that for all $n \geq n_0$, $P\{|T| = n\} > 0$, so that size conditioning is possible. If $d > 1$, then there exists $n_0$ such that for all $n \geq n_0$ such that $n - 1$ is a multiple of $d$, $P\{|T| = n\} > 0$. We call $\mathcal{N}$ the set of integers $n$ for which $P\{|T| = n\} > 0$, and will assume that $n \in \mathcal{N}$.

The algorithms of this paper apply for all distributions of $\xi$. We are particularly interested in those for which $\xi$ is not monoatomic (to avoid trivialities). A particularly important class is those for which

$$0 < \sigma^2 \overset{\text{def}}{=} V\{\xi\} < \infty.$$  

At the end of the paper, we will briefly deal with $\xi$ that do not have finite variance or even finite mean.

Finally, many complexity results depend upon the parameters $\phi_n$ and $\tau_n$ defined by

$$\phi_n = P\{\xi_1 + \cdots + \xi_n = n - 1\}, \tau_n = E\{\max(\xi_1, \ldots, \xi_n)\},$$

where $\xi_1, \ldots, \xi_n$, as elsewhere in the paper, are i.i.d. random variables distributed as $\xi$. It is well-known (see, e.g., Kolchin, 1986, or Petrov, 1975, 1995), that if $0 < \sigma < \infty$,

$$\phi_n = \frac{(d + o(1))^{1/\mathcal{N}}}{\sigma \sqrt{2\pi n}}.$$  

Assuming a RAM model of computation, and assuming that independent copies of $\xi$ can be generated in expected time 1, the main result of the paper is as follows.

**Theorem 1.** There exists an algorithm for generating $T$ conditional on $|T| = n$ in expected time bounded from above by a constant times

$$n + 1 + \tau_n, \tau_n \in \mathcal{N}.$$  

In particular, if $E\{\xi^2\} < \infty$, then $\tau_n = o(\sqrt{n})$, $\phi_n = \Theta(1/\sqrt{n})$ and thus, the expected time is $O(n)$.  

3
In this paper, we were tempted to use the terminology “Bienaymé tree” instead of the widely accepted name “Galton-Watson tree”, as it increasingly clear that Bienaymé defined and derived the main properties of these trees almost fifty years before Galton and Watson (see, e.g., Kendall, 1975).

We first review two natural attempts that have superlinear expected complexity. The final algorithm uses ingredients from these simple methods, but adds a key ingredient—the multinomial method,—which permits the problem to be split into one of generating a certain multinomial random vector, and then applying a uniform random permutation. The first term \(n\) in the expected complexity of Theorem 1 comes from the uniform random permutation—it does not depend upon \(\xi\). The \(\tau_n/\varphi_n\) term in Theorem 1 comes from the multinomial part of the algorithm. Interestingly, if \(E\{\xi^2\} < \infty\), it is \(o(n)\). Therefore, the speed of execution is basically determined by the uniform random permutation generator.

The naive method

A tree \(T\) can be traversed in DFS (depth first search) order. If we do so, we may keep a list of the number of offspring, \(\xi_1, \xi_2, \ldots\). Vice versa, a tree \(T\) can be constructed from a sequence \(\xi_1, \xi_2, \ldots\) in this manner. The latter process can be viewed sequentially: start with a root node and put it in a queue. At the \(i\)-th step, grab the first node from the queue, give it \(\xi_i\) children, and place these in the queue. The process ends when the queue is empty. It ends with a tree \(T\) of correct size \(n\) when the queue becomes empty for the first time after the \(n\)-th step.

Let \(T\) denote the tree generated by this process. From a sequence \(\xi_1, \xi_2, \ldots, \xi_n\), we can generate \(T\) if \(|T| = n\) and decide that \(|T| > n\) otherwise. Thus, stopping after the \(n\)-th step or when the queue becomes empty for the first time has complexity \(\min(|T|, n)\).

We can repeat the above procedure this until for the first time \(|T| = n\). By Wald’s lemma, the expected complexity is the expected number of iterations times \(E\{\min(|T|, n)\}\). The expected number of iterations is \(1/P\{|T| = n\}\). We know (see, e.g., Kolchin, 1986) that

\[
P\{|T| = n\} = \frac{\varphi_n}{n}.
\]

And then,

\[
E\{\min(|T|, n)\} = \sum_{i=1}^{n} \varphi_i + nP\{|T| > n\}.
\]

By Wald’s identity, the expected complexity is asymptotic to

\[
\frac{E\{\min(|T|, n)\}}{P\{|T| = n\}} \approx n \sum_{i=1}^{n} \frac{\varphi_i}{\varphi_n} + n^2 \sum_{i=n+1}^{\infty} \frac{\varphi_i}{i \varphi_n}.
\]

Under the condition \(0 < \sigma < \infty, n \in \mathcal{N}\), it is easy to see that \(\varphi_n = \Theta(1/\sqrt{n})\), \(P\{|T| = n\} = \Theta(n^{-3/2})\), and thus that the expected complexity is \(\Theta(n^2)\).
Turning to random walks

The size of the queue after the $t$-th step above is denoted by $S_t$. Thus, $S_0 = 1$, and

$$S_t = S_{t-1} + (\xi_t - 1) = 1 + \sum_{i=1}^{t} (\xi_i - 1), \quad t > 0.$$ 

This provides the well-known random walk construction of Galton-Watson trees. The size of the Galton-Watson tree $T$ generated in this manner is

$$|T| = \min\{t : S_t = 0\}.$$ 

But $T$ is, of course, an unconditional Galton-Watson tree. For a conditional tree, we are interested in sequences $\xi_1, \xi_2, \ldots$ with $|T| = n$. A necessary condition for this is that

$$\Xi \overset{\text{def}}{=} (\xi_1, \ldots, \xi_n)$$ 

has sum

$$S(\Xi) \overset{\text{def}}{=} \sum_{i=1}^{n} \xi_i = n - 1.$$ 

This implies that $|T| \leq n$. However, there is one and only one rotation of $\Xi$, i.e., a vector

$$\Xi(\ell) \overset{\text{def}}{=} (\xi_\ell, \xi_{\ell+1}, \ldots, \xi_n, \xi_1, \ldots, \xi_{\ell-1})$$

with the required property that $|T| = n$. This follows from the standard rotation argument for partial sums, sometimes referred to as the Dvoretzky-Motzkin cycle lemma (see, e.g., Comtet (1994) or Derhowitz and Zaks (1990)). Following Figure 1, $\ell$ is the smallest index in $\{1, \ldots, n\}$ at which $S_t$ reaches its minimum:

$$\ell = \arg \min\{S_t : 1 \leq t \leq n\}.$$ 

It is easy to verify that $\Xi(\ell)$ has $S_t \geq 1$ for $0 \leq t < n$ and $S_n = 0$. Furthermore, $|T| < n$ for all $\Xi(s)$, $s \neq \ell$. 
Figure 1. Top figure shows a random walk from (0, 1) to (n, 0). By starting the walk at the leftmost minimal node (blackened), the walk stays strictly positive until just before the last step, and thus corresponds uniquely to an ordered (Galton-Watson) tree of size n.
This observation implies a routine strategy for simulation: keep generating random sequences \( \Xi \) of length \( n \) until \( S(\Xi) = n - 1 \). Then rotate \( \Xi \) (in linear time) to get \( \Xi(\ell) \) with \( |T| = n \). The tree that corresponds to \( \Xi(\ell) \) is a conditional Galton-Watson tree of size \( n \).

It is well-known that if \( \xi \) is not monoatomic, then

\[
\varphi_n \leq \sup_x P\{S_n = x\} \leq \frac{c}{\sqrt{n}},
\]

where \( c > 0 \) depends upon the distribution of \( \xi \) only. This follows, for example, from general upper bounds for the concentration of mass of sums of independent random variables: see, e.g., Petrov (1975, p. 49). When \( \sigma^2 < \infty \), the order of this bound in \( n \) is correct, but for \( \sigma = \infty \), the upper bound is \( o(1/\sqrt{n}) \) (Petrov, p. 46).

Thus, for any distribution, the procedure outlined here takes expected time

\[
\frac{n}{P\{S(\Xi) = n-1\}} = \frac{n}{\varphi_n} = \Omega(n^{3/2}).
\]

Furthermore, since \( \mathbb{E}\{\xi = 1\} \), we have for increasing \( n \) drawn from \( \mathcal{N} \), whenever \( \sigma^2 < \infty \), \( \varphi_n = \Theta(1/\sqrt{n}) \) (see, e.g., Kolchin, 1986), and thus the expected time is \( \Theta(n^{3/2}) \).

**Remark: Dwass’s formula.** This construction makes Dwass’s formula (Dwass, 1969) explicit:

\[
P\{S_1 > 0, \ldots, S_{n-1} > 0, S_n = 0\} = \frac{1}{n} P\{|T| = n\} = \frac{1}{n} P\{S_n = 0\} = \frac{1}{n} P\{\xi_1 + \cdots + \xi_n = n - 1\} = \frac{\varphi_n}{n}.
\]

**Generating random samples conditional on the sum**

The previous section points up the importance of a fast method for generating a sequence

\[
\Xi \overset{\text{def}}{=} (\xi_1, \ldots, \xi_n)
\]

of i.i.d. integer-valued random variables distributed as \( \xi \geq 0 \), conditional on

\[
S(\Xi) \overset{\text{def}}{=} \sum_{i=1}^{n} \xi_i = n - 1.
\]

This is a problem of independent interest. In some cases, there are simple explicit solutions. For example, when \( \xi \) is Poisson \((\lambda)\) (for any fixed \( \lambda > 0 \)), then the conditional law of \( \Xi \) is multinomial \((n-1, 1/n, \ldots, 1/n)\). This leads to an extremely simple procedure: generate \( n - 1 \) i.i.d. random integers \( Z_1, \ldots, Z_{n-1} \) uniformly drawn from \( \{1, \ldots, n\} \), Then set

\[
\xi_i = \sum_{j=1}^{n-1} 1[|Z_j - i|] , 1 \leq i \leq n.
\]

This yields the vector \( \Xi \). By the rotation method of the previous section, we thus have a very simple linear time method for generating a random Cayley tree.

Let us concentrate however on generating \( S(\Xi) \). There is a literature on this, which was reviewed and summarized in Devroye (1986, 1988). Under certain conditions, and for certain computational models,
one can generate \( S(\Xi) \) in expected time \( O(1) \). However, for the purpose of the present paper, and this section, one simple paradigm stands out—the multinomial method. It provides a versatile tool for generating \( S(\Xi) \) in sublinear time. For this method, still using \( p_i = P(\xi = i), i \geq 0 \), we first generate the multinomial random vector \((N_0, N_1, N_2, \ldots)\) with parameter \((n, p_0, p_1, p_2, \ldots)\), and the note that

\[
S(\Xi) = \sum_{i=0}^{\infty} iN_i.
\]

Now, \( N_0 \) is binomial \((n, p_0)\). Conditional on \( N_0 \), \( N_1 \) is binomial \((n - N_0, p_1/(1 - p_0))\), and so forth. In this manner, we can generate the random multinomial vector \((N_0, \ldots, N_K)\), where \( K \) is the last populated (nonzero) component, i.e., \( N_j = 0 \) for \( j > K \). The expected time for generating \((N_0, \ldots, N_K)\) is

\[
E\{1 + K\} = 1 + E\left\{ \max_{1 \leq i \leq n} \xi_i \right\} = 1 + \tau_n
\]

It is a simple exercise to show that when \( E\{\xi\} < \infty \), then this is \( o(n) \). However, the situation is typically much better. If \( \xi \) has compact support, then the expected time is \( O(1) \). A simple bound can be derived in terms of the \( \rho \)-th moment, \( \rho > 1 \):

\[
\tau_n \leq E\left\{ \left( \sum_{1 \leq i \leq n} \xi_i^\rho \right)^{1/\rho} \right\}
\]

\[
\leq \left( E\left\{ \sum_{1 \leq i \leq n} \xi_i^\rho \right\} \right)^{1/\rho}
\]

\[
= (nE\{\xi^\rho\})^{1/\rho}
\]

\[
= O\left(n^{1/\rho}\right)
\]

when \( E\{\xi^\rho\} < \infty \). We leave it as an exercise to show that \( \tau_n = o\left(\left(n^{1/\rho}\right)\right) \) under the latter condition.

Assume that we repeat the above procedure until for the first time \( S(\Xi) = n - 1 \). Then the sum is correct, and we have, as a by-product, a random multinomial vector \((N_0, N_1, \ldots, N_K)\). This vector has the frequencies of occurrences of the \( \xi_i \)'s, i.e., there are \( N_0 \) zeroes, \( N_1 \) ones, and so forth. Note that

\[
\sum_{i=1}^{n} \xi_i = \sum_{j=0}^{K} jN_j = n - 1,
\]

as required. The remainder of the algorithm is trivial: just fill an array of length \( n \) with \( N_j \) values \( j \), \( 0 \leq j \leq K \), and randomly permute it. Random permutations of arrays are easy to implement in situ in linear time—see, e.g., Knuth (1981). The permuted array contains the sought vector \( \Xi \).
By Wald’s lemma, the expected time until we have $S(n) = n - 1$ is bounded by

$$
\frac{1 + \tau_n}{P\{S(n) = n - 1\}} = \frac{1 + \tau_n}{\varphi_n}.
$$

For example, if $\mathbb{E}\{\xi^2\} < \infty$, then $\varphi_n = \Theta(1/\sqrt{n})$, and the numerator is $O(\sqrt{n})$, for a total of $O(n)$. However, if $\mathbb{E}\{\xi^\rho\} < \infty$ for fixed $\rho > 2$, then the numerator is $O(n^{1/\rho})$ as pointed out above, and the expected time bound becomes $O(n^{1/2 + 1/\rho})$.

**Remark:** Infinite variance. The behavior of $\varphi_n$ depends upon $\xi$. If the variance of $\xi$ is infinite, but $\mathbb{E}\xi = 1$, the complexity of the algorithm is still acceptable. To get an idea of this, let $\phi$ be the characteristic function of $\xi - 1$ (which is of mean zero). If $d$ is the span of $\xi$, an inversion formula for the characteristic function (see, e.g., Petrov, 1995, p. 15) shows that

$$
\varphi_n = \frac{d}{2\pi} \int_{|t|<\pi/d} e^{it\phi^n(t)} \, dt.
$$

If $\xi$ is in the domain of attraction of a stable of parameter $\alpha \in (1, 2]$, and in particular, if $\phi(t) = \exp(-|t|^\alpha(1 + o(1)))$, then standard calculations show that

$$
\varphi_n = \Theta\left(n^{-1/\alpha}\right).
$$

**Remark:** Infinite mean. If $\mathbb{E}\xi = \infty$, while the algorithm is still valid, the complexity becomes rather unpleasant. To deal with this case, a lot more work is needed to deal with the efficient generation of size-constrained Galton-Watson trees.

**Generating random forests**

Random forests can be defined in a number of ways, see, e.g., Pavlov (2000). In the context of the present paper, the most important model is that of a random forest of $k$ Galton-Watson trees of total size $n$. Each tree has at least a root, and thus, $n \geq k$ is understood. If the span of $\xi$ is $d$, then $n - k$ is necessarily a multiple of $d$. The set of all $n$ that are possible, given the distribution of $\xi$, is $\mathcal{N}$, and $n \in \mathcal{N}$ is understood throughout.

The random forest of interest to us is a collection of non-empty independent Galton-Watson trees $T_1, \ldots, T_k$ conditional on $|T_1| + \cdots + |T_k| = n$. Here too we can make a unique connection with sequences $\xi_1, \ldots, \xi_n$ drawn independently from the distribution of $\xi$. Each such sequence corresponds to such a random forest provided that

$$
\sum_{i=1}^{n} \xi_i = n - k.
$$

The construction generalizes that for the random tree in a natural manner. Random walks are now started with a queue having $k$ elements: $S_0 = k$. Then we proceed as before, and form

$$
S_t = k + \sum_{i=1}^{t} (\xi_i - 1).
$$
Note that at $t = n$, we have precisely $k$ trees in the forest if and only if $S_t > 0$ for all $t < n$ and $S_n = 0$. Since $S_t$ decreases by at most one, this means that if this condition is satisfied, $S_t$ passes through each of the values $k - 1, k - 2, \ldots, 1$ and 0 for the first time, say at $t = t_{k-1}$, $t = t_{k-2}, \ldots, t = t_0$. Each of these integers wraps up the construction of one tree in the forest, so the tree sizes are $t_{k-1}, t_{k-2}, t_{k-1}, \ldots, t_0 - t_1$.

If $S_n = 0$, the condition $S_t > 0$ for all $t < n$ may not be satisfied. When this happens, there is one (and only one) rotation that insures that for the rotated sequence, $S_t > 0$ for all $t < n$. This is illustrated in Figure 2: find the first $t \geq 0$ for which $S_t = \min_{1 \leq i \leq n} S_i$. Then rotate by starting a new random walk at $t$. This walk, and only this one among all rotated walks, has the desired property. It is then easy to see that we can apply all algorithms of this paper towards random forest generation. For the analysis, note that the crucial parameter $\varphi_n$ now is

$$\varphi_n = \mathbb{P}\{\xi_1 + \cdots + \xi_n = n - k\}.$$ 

It is well-known (see, e.g., Kolchin, 1986, or Petrov, 1975, 1995), that if $0 < \sigma < \infty$,

$$\varphi_n = \frac{(d + o(1))e^{-k^2/(2\sigma^2n)}1_{[n \in \mathbb{N}]}}{\sigma\sqrt{2\pi n}}.$$ 

This behaves as the old $\varphi_n$ when $k = o(\sqrt{n})$. Interestingly, the expected complexity for finite $\sigma$ is $O(n)$ even if $k$ varies with $n$ such that $k = o(\sqrt{n})$. 

10
Figure 2. Top figure shows a random walk from $(0, k)$ to $(n, 0)$. By starting the walk at the leftmost minimal node (blackened), the walk results in a clean separation (bottom) into $k$ trees. For each tree, as we know, a walk started at $(0, 1)$ ends when for the first time a node of height 0 is reached.
